Abstract

This paper addresses the challenge of real-time obstacle avoidance for nonlinear vehicle systems subjected to external disturbances with unknown or mismatched distributions. To tackle this critical safety issue, we propose a distributionally robust model predictive control (DR-MPC) strategy based on the Koopman operator. Initially, the Koopman operator is utilized to elevate the nonlinear vehicle dynamics into a high-dimensional latent space, thereby achieving global linearization and facilitating efficient control design for real-time applications. Subsequently, we define a Wasserstein ambiguity set to characterize the uncertainty in disturbance distributions, formulating the control problem as a min-max optimization to ensure robustness against distributional shifts. Furthermore, the probabilistic obstacle avoidance constraint is equivalently transformed into a tractable Conditional Value-at-Risk (CVaR) constraint, supported by established theoretical lemmas, which allows for real-time solutions via standard convex solvers. Finally, extensive simulations on nonlinear vehicle models in both static and dynamic obstacle scenarios validate the proposed approach, demonstrating superior performance compared to traditional linear MPC and stochastic Koopman MPC in terms of safety (zero constraint violations) and real-time feasibility.

Keywords:
Nonlinear Vehicle Dynamics, Distributionally Robust Model Predictive Control, Koopman Operator, Disturbance Uncertainty, Racing Vehicle, CVaR.

1. INTRODUCTION

1.1. Research Background

In recent years, autonomous driving has emerged as a transformative technology, applied to an increasingly diverse range of driving scenarios. However, compared to common urban and highway driving situations, the automatic control of race cars presents significant differences. In extreme dynamic scenarios such as real-time racing control, there are exceptionally high demands on the system's perception, decision-making, and control capabilities. Nevertheless, the safe deployment of such scenarios in complex real-world environments is hindered by two key challenges: the inherent nonlinearity of vehicle dynamics and the unknown or mismatched distribution of external disturbances. On a racetrack, vehicles frequently operate at the limits of tire adhesion during high-speed cornering, emergency obstacle avoidance, etc., where the dynamics exhibit strong nonlinear characteristics. Simultaneously, factors such as variations in track surface friction coefficients, crosswind disturbances, and the uncertain behavior of other racing vehicles make it difficult to accurately model the statistical properties of disturbances.

Traditional linearization techniques (e.g., Taylor expansion) are only valid near equilibrium points and fail to capture global vehicle behavior during safety-critical maneuvers like real-time obstacle avoidance. Conventional stochastic control relies on known disturbance distribution assumptions, which can lead to catastrophic outcomes when the distribution is mismatched. While deterministic robust control can guarantee safety in the worst-case scenario, it often proves too conservative to meet the extreme performance demands of racing.

In recent years, Koopman operator theory has provided a new perspective for solving nonlinear control problems. By lifting the state to a high-dimensional latent space, it enables the global linearization of nonlinear systems, thus allowing the application of linear control methods while preserving the integrity of the dynamics. Concurrently, Distributionally Robust Model Predictive Control (DR-MPC) characterizes disturbance uncertainty by constructing an ambiguity set containing possible true distributions, considering the worst-case distribution within the optimization objective to effectively balance performance and robustness. However, the systematic integration of these two methods for nonlinear vehicle obstacle avoidance control, particularly concerning the tractability of probabilistic safety constraints in real-time racing control scenarios, still requires further in-depth investigation.

While existing works have explored Koopman-based MPC [6]–[8] and distributionally robust control [9]–[11] separately, the integration of these two paradigms—especially with CVaR constraints imposed directly on the lifted disturbances—remains unexplored. This paper fills this gap by proposing a unified framework that combines the linearization power of Deep Koopman with the robustness guarantees of Wasserstein DRO, achieving superior safety performance in vehicle obstacle avoidance.

To address this gap, this paper proposes a Distributionally Robust Koopman Model Predictive Control strategy. This framework first utilizes the Koopman operator to achieve global linearization of nonlinear vehicle dynamics. Subsequently, it employs the Wasserstein distance to construct an ambiguity set for the disturbance distribution, describing the distributional uncertainty within a minimax optimization framework. Finally, the probabilistic obstacle avoidance constraints are equivalently transformed into tractable Conditional Value-at-Risk (CVaR) constraints, ensuring high-probability satisfaction of safety constraints under uncertainty. Extensive simulation validations on nonlinear vehicle models demonstrate that the proposed method outperforms traditional linear Model Predictive Control and stochastic Koopman Model Predictive Control in terms of safety and real-time feasibility, making it particularly suitable for real-time racing obstacle avoidance scenarios with stringent requirements for response speed and reliability.

1.2. Related Works

The Koopman operator has become a promising tool for handling nonlinear vehicle dynamics by lifting states to a high-dimensional latent space for global linearization, with relevant studies (e.g., Manzoor et al. [A], Alcalá et al.) summarizing its vehicular applications and demonstrating its feasibility for real-time obstacle avoidance in autonomous scenarios. For nonlinear vehicle motion planning and obstacle avoidance, Alcalá et al. further proposed an LPV-based model predictive planning approach for autonomous racing, which reformulates nonlinear vehicle dynamics into pseudo-linear LPV form via objective convexification, achieving reduced computational load while maintaining high-performance velocity maximization and obstacle avoidance under state/input constraints. Parallelly, distributionally robust optimization (DRO) via Wasserstein ambiguity sets—pioneered by Esfahani and Kuhn [B]—effectively addresses unknown disturbance distributions, with extensions (e.g., Hakobyan and Yang) to CVaR-based collision avoidance for autonomous vehicles. The integration of Koopman and DR-MPC has also

been explored, with a dedicated K-DRMPC framework proposed to linearize nonlinear systems via the Koopman operator and reformulate state chance constraints into tractable Second-Order Cone (SOC) constraints for robust control under disturbances; however, this work only characterizes uncertainties using first and second-order moment information estimated from empirical data, a restrictive assumption that fails to capture the full complexity of real-world disturbance distributions in autonomous driving. Notably, unlike such Koopman-DRMPC variants with oversimplified uncertainty modeling, and distinct from LPV approaches (including the racing-oriented method by Alcalá et al.) that rely on local pseudo-linearization via scheduling variables and convexification to approximate nonlinear dynamics, our Koopman-based DR-MPC method achieves rigorous global linearization in a high-dimensional latent space and adopts Wasserstein ambiguity sets to model disturbance uncertainty, avoiding both the inherent approximation errors of LPV and the restrictive moment assumptions of existing K-DRMPC frameworks while still ensuring real-time computational efficiency for safety-critical obstacle avoidance.

1.3. Contributions

The contributions of our paper are presented as follows:

i) A Koopman-based linearization framework is designed for real-time obstacle avoidance. The Koopman operator is employed to lift inherently nonlinear vehicle dynamics into a high-dimensional latent space, achieving global linearization that breaks the local validity limitation of traditional Jacobian linearization. It can be practically implemented via Extended Dynamic Mode Decomposition (EDMD) or deep neural networks (Deep Koopman), enabling direct application of linear control theories and improving modeling accuracy for fast obstacle avoidance.

ii) A safety-oriented distributionally robust MPC (DR-MPC) strategy is proposed to address unknown or mismatched disturbance distributions. A Wasserstein ambiguity set is defined to characterize disturbance uncertainty, and the control problem is cast as a min-max optimization to minimize the worst-case expected cost over plausible distributions, avoiding the over-conservatism of deterministic robust MPC and strong distribution assumptions of stochastic MPC.

iii) An equivalent Conditional Value-at-Risk (CVaR) reformulation is presented for probabilistic obstacle avoidance constraints. Leveraging the equivalence between chance constraints and CVaR under the Wasserstein ambiguity set, the intractable probabilistic constraint is converted into a convex form, which is solvable via standard convex solvers to meet real-time control requirements.

iv) Extensive simulations are conducted to validate the proposed framework on nonlinear vehicle models in static and dynamic obstacle environments with distribution shifts. Comparisons with traditional linear MPC and stochastic Koopman MPC demonstrate the superior safety performance and real-time feasibility of the proposed method.

1.4. Paper Organization

The rest of this paper is organized as follows:

i) Section 2 formulates the nonlinear vehicle dynamic model and introduces the Koopman operator-based lifting approach to linearize the nonlinear system in a high-dimensional latent space, while defining the probabilistic obstacle avoidance constraint for safety-critical control.

ii) Section 3 presents the detailed design of the distributionally robust MPC controller, including the definition of the Wasserstein ambiguity set, the min-max optimization formulation, and the CVaR reformulation of the probabilistic obstacle avoidance constraint to achieve tractable real-time solution.

iii) Section 4 conducts extensive simulation experiments to validate the effectiveness and real-time performance of the proposed approach, comparing it with baseline methods under static and dynamic obstacle scenarios.

iv) Finally, Section 5 summarizes the main contributions of this paper and outlines potential future research directions.

2. RACING VEHICLE MODEL AND OBSTACLE AVOIDANCE

2.1. Nonlinear Vehicle Dynamics for Racing

A variety of vehicle dynamics models have been developed to characterize the motion of ground vehicles, ranging from simple kinematic bicycle

models to high-fidelity multibody formulations. While these models offer varying levels of accuracy and complexity, they inevitably rely on simplifying assumptions—such as linear tire behavior, constant friction coefficients, or idealized suspension kinematics—that introduce a gap between the nominal model and the actual physical system. This discrepancy, often referred to as model mismatch, can significantly degrade control performance, particularly in safety-critical scenarios such as high-speed racing or emergency obstacle avoidance.

In response to these limitations, data-driven approaches have recently attracted considerable attention from both academia and industry. By leveraging measurement data, these methods aim to either learn the system dynamics directly or compensate for the residual errors left by first-principles models. The growing availability of onboard sensors and computational resources has further accelerated the adoption of data-driven techniques in real-world applications, including autonomous driving, advanced driver-assistance systems, and motorsport engineering.

The bicycle model is a widely used simplified representation of vehicle dynamics in high-performance and racing scenarios. By reducing the four-wheel configuration to an equivalent two-wheel structure, it captures the essential lateral and longitudinal behavior while remaining computationally efficient. Despite its simplicity, the model retains key nonlinear effects such as tire force saturation and high-speed cornering dynamics, making it suitable for obstacle avoidance and fast trajectory tracking. This model also provides a practical foundation for later Koopman-based lifting, where the nonlinear dynamics are embedded into a higher-dimensional latent space for globally linear control design.

2.2. Problem Formulation

To describe the vehicle motion at moderate to high speeds, we consider the kinematic bicycle model, which captures the essential geometric relationship between velocity, steering angle, and vehicle orientation without relying on tire force equations.

$$x_{t+1} = f(x_t, u_t, w_t).$$

This equation describes the evolution of the vehicle from time step t to $t+1$ under the nonlinear dynamics $f(\cdot)$, which is defined by the kinematic bicycle model.

The variables are defined as:

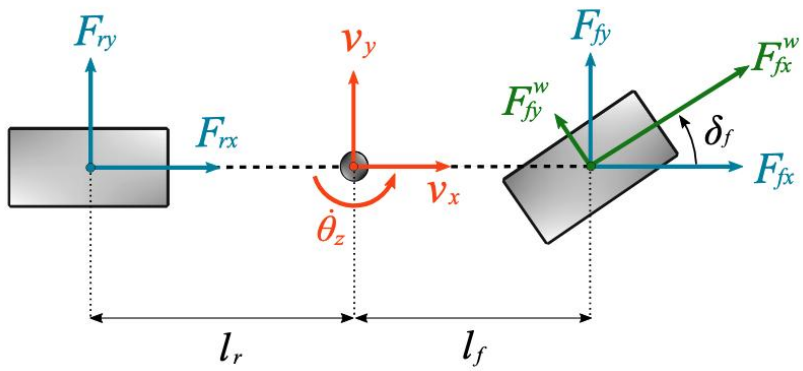

Figure 1: Vehicle Dynamics

- $x_t \in \mathbb{R}^5$ denotes the state vector, defined as:

$$x_t = \begin{bmatrix} p_x & p_y & v & \psi & \omega \end{bmatrix}^\top,$$

  where $t \in \{0, 1, \ldots, T\}$ are discrete time steps, p_x and p_y are the global position coordinates, v is the longitudinal velocity, ψ is the yaw angle, and ω is the yaw rate.

- $u_t \in \mathbb{R}^2$ denotes the control input, defined as:

$$u_t = \begin{bmatrix} a & \delta \end{bmatrix}^\top,$$

  where a is the acceleration (positive for throttle, negative for braking) and δ is the steering angle.

- $w_t \in \mathbb{R}^5$ denotes the disturbance vector, defined as:

$$w_t = \begin{bmatrix} w_{p_x} & w_{p_y} & w_v & w_\psi & w_\omega \end{bmatrix}^\top,$$

  capturing the effect of exogenous uncertainties affecting the vehicle dynamics, including road irregularities, wind gusts, tire-road friction variations, and model mismatches between the nominal dynamics and the real system.

2.3. MPC Formulation

The nominal MPC problem for vehicle obstacle avoidance is formulated as follows. Let $x_t \in \mathbb{R}^5$ denote the state, $u_t \in \mathbb{R}^2$ the control input, and

$w_t \in \mathbb{R}^5$ the exogenous disturbance. The discrete-time nonlinear dynamics are given by:

$$x_{t+1} = f(x_t, u_t) + w_t, \quad \forall t \in \mathbb{Z}_{0:T-1}. \tag{2.1}$$

The state constraint set $\mathcal{X} \subset \mathbb{R}^5$ encodes physical limits and safety requirements:

$$\mathcal{X} = \left\{ x = [p_x, p_y, v, \psi, \omega]^\top \in \mathbb{R}^5 \;\middle|\; \begin{array}{l} d_{\text{track}}(p_x, p_y) \geq 0, \\ \|[p_x, p_y]^\top - o_j\| \geq d^j_{\text{safe}}, \ \forall j, \\ v_{\min} \leq v \leq v_{\max} \end{array} \right\}.$$

The control input set $\mathcal{U} \subset \mathbb{R}^2$ reflects actuator limits:

$$\mathcal{U} = \left\{ u = [a, \delta]^\top \in \mathbb{R}^2 \;\middle|\; a_{\min} \leq a \leq a_{\max}, \ |\delta| \leq \delta_{\max} \right\}.$$

The steering rate is additionally constrained by actuator dynamics:

$$|\delta_{t+1} - \delta_t| \leq \Delta\delta_{\max}\Delta t, \quad \forall t \in \mathbb{Z}_{0:T-2}. \tag{2.2}$$

The objective is to track a reference trajectory while minimizing control effort:

$$\min_{\{u_t\}_{t=0}^{T-1}} \sum_{t=0}^{T-1} \left(\|x_t - x_t^{\text{ref}}\|_Q^2 + \|\Delta u_t\|_R^2 \right), \tag{2.3}$$

where $\Delta u_t = u_t - u_{t-1}$.

The nominal MPC problem is thus:

$$\begin{aligned} \min_{\{u_t\}} \quad & \sum_{t=0}^{T-1} \left(\|x_t - x_t^{\text{ref}}\|_Q^2 + \|\Delta u_t\|_R^2 \right) \\ \text{s.t.} \quad & x_{t+1} = f(x_t, u_t) + w_t, \quad \forall t, \\ & x_0 = x_{\text{current}}, \\ & x_t \in \mathcal{X}, \quad \forall t, \\ & u_t \in \mathcal{U}, \quad \forall t, \\ & |\delta_{t+1} - \delta_t| \leq \Delta\delta_{\max}\Delta t, \quad \forall t. \end{aligned} \tag{2.4}$$

This formulation serves as the baseline for the data-driven and distributionally robust extensions developed in Sections III and IV.

3. DATA-DRIVEN DEEP KOOPMAN MODEL

3.1. Koopman operator basics

The Koopman operator theory offers a systematic way to obtain a linear representation of nonlinear dynamics by lifting the state to a space of observables. Consider a discrete-time nonlinear system:

$$x_{t+1} = f(x_t, u_t).$$

The Koopman operator $\mathcal{K}$ acts on scalar observable functions $\psi : \mathbb{R}^{n_x} \to \mathbb{R}$ as:

$$\mathcal{K}\psi(x) = \psi(f(x, u)).$$

Although the original dynamics are nonlinear, the evolution of observables under $\mathcal{K}$ is linear. In practice, we approximate this infinite-dimensional operator by selecting a finite set of observables $\phi(x) = [\phi_1(x), \ldots, \phi_{n_z}(x)]^\top$, leading to a lifted state $z = \phi(x)$ with approximately linear dynamics:

$$z_{t+1} \approx Az_t + Bu_t.$$

This lifted linear representation enables the use of linear MPC techniques for nonlinear systems, which is the foundation of our approach.

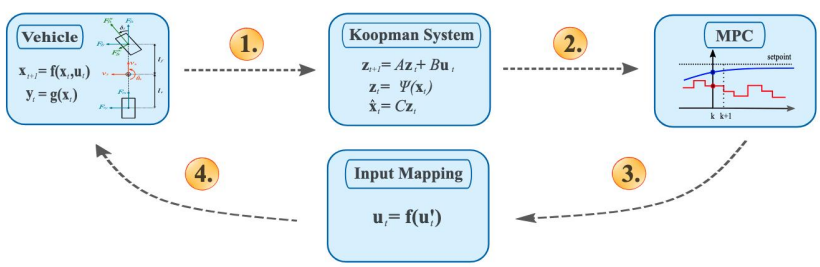

Figure 2:

3.2. Extended Dynamics Mode Decomposition

Extended Dynamic Mode Decomposition (EDMD) provides a data-driven framework for approximating the Koopman operator by lifting the original state into a space of observable functions. Let $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{M}$ be a set of snapshot pairs, where $y_i = f(x_i)$ for autonomous systems, or $y_i = f(x_i, u_i)$ for

controlled systems. The core idea is to choose a set of basis functions $\Psi(x) = [\psi_1(x), \ldots, \psi_{N_\psi}(x)]^\top$ and seek a matrix K that minimizes the residual:

$$\min_K \sum_{i=1}^{M} \|\Psi(y_i) - K\Psi(x_i)\|_2^2.$$

This least-squares problem admits a closed-form solution:

$$K = G^+ A,$$

where $G = \frac{1}{M}\sum_{i=1}^{M} \Psi(x_i)\Psi(x_i)^\top$ is the Gram matrix, $A = \frac{1}{M}\sum_{i=1}^{M} \Psi(y_i)\Psi(x_i)^\top$ is the cross-covariance matrix, and G^+ denotes the pseudoinverse. The choice of basis functions Ψ is critical: it determines the quality of the linear approximation and the dimensionality of the lifted space.

While EDMD offers a principled way to approximate the Koopman operator from data, its reliance on handcrafted basis functions (e.g., polynomials, radial basis functions) often limits its expressiveness, especially for high-dimensional or strongly nonlinear systems. Moreover, the number of basis functions grows combinatorially with the state dimension, leading to the curse of dimensionality. These limitations motivate the use of neural networks to learn the lifting functions adaptively—a paradigm known as Deep Koopman, which we adopt in this work.

3.3. Deep Koopman Training Framework

Compared to the classic EDMD, the Deep Koopman model uses a deep neutral network to generate the observable subspace of the Koopman operator.

The Deep Koopman model adopts an encoder-decoder structure. The goal is to learn a lifting function $\phi(\cdot)$ and a linear dynamics matrix $\mathcal{K}$ such that the evolution in the lifted space approximates the true nonlinear dynamics. Unlike the original framework which operates on traffic flow states, we adapt it to vehicle dynamics by defining the state vector $x_t = [p_x, p_y, v, \psi, \omega]^\top$.

3.3.1. Koopman Encoder-Decoder Architecture

The Deep Koopman model consists of three components:

- **Encoder** $\phi(\cdot)$: A feedforward neural network mapping the physical state x_t to a latent representation $z_t \in \mathbb{R}^{n_z}$. We adopt a 3-layer architecture with $[64, 128, 64]$ units and ReLU activations. Or LSTM network?

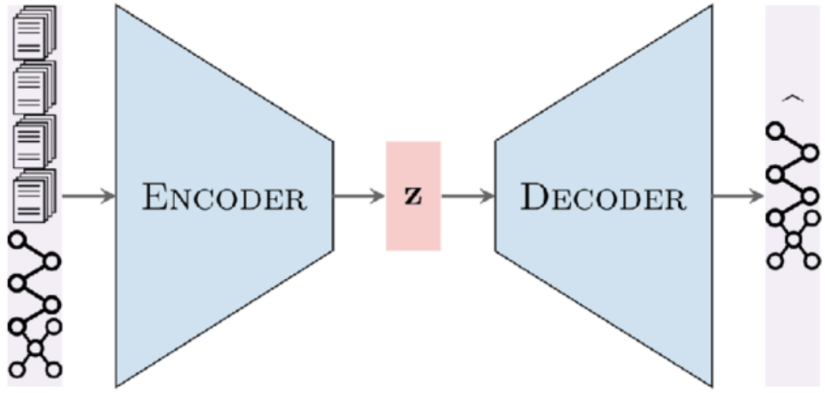

Figure 3: Encoder-Decoder Architecture

- **Linear Dynamics** $\mathcal{K}$: A learnable matrix $A \in \mathbb{R}^{n_z \times n_z}$ governing the evolution in the latent space: $z_{t+1} = Az_t + Bu_t + Cw_t$, where B and C are also learnable.
- **Decoder** $\psi(\cdot)$: A neural network reconstructing the physical state from the latent representation, with architecture $[64, 32]$ and ReLU activations.

3.3.2. Encoder Network

The encoder $\phi_{\theta_e} : \mathbb{R}^{n_x} \to \mathbb{R}^{n_z}$ maps the physical state x_t to a latent representation z_t. We design a feedforward neural network with the following structure:

Layer	**Units**	**Activation**
Input	$n_x = 5$	—
Hidden 1	64	ReLU
Hidden 2	128	ReLU
Hidden 3	64	ReLU
Output	$n_z = 32$	Linear

Table 1: Encoder network architecture.

3.3.3. Linear Dynamics Layer

In the latent space, we enforce linear evolution:

$$z_{t+1} = Az_t + Bu_t + Cw_t,$$

where $A \in \mathbb{R}^{n_z \times n_z}$, $B \in \mathbb{R}^{n_z \times n_u}$, and $C \in \mathbb{R}^{n_z \times n_x}$ are learnable matrices. Unlike the encoder and decoder, these matrices are **linear** and do not contain activation functions. They can be implemented as fully connected layers without bias and with linear activation.

This linear structure is the key insight of the Koopman operator framework: by lifting the state to a sufficiently high-dimensional latent space, the nonlinear dynamics become approximately linear, enabling the use of efficient linear control techniques.

3.3.4. Decoder Network

The decoder $\psi_{\theta_d} : \mathbb{R}^{n_z} \to \mathbb{R}^{n_x}$ reconstructs the physical state from the latent representation:

$$\hat{x}_{t+1} = \psi_{\theta_d}(z_{t+1}),$$

where $\hat{x}_{t+1}$ is the reconstructed next state. The architecture is symmetric to the encoder but with fewer layers, as the reconstruction task is generally less demanding than the lifting task.

Table 2: Decoder network architecture.

Layer	**Units**	**Activation**
Input	$n_z = 32$	—
Hidden 1	64	ReLU
Hidden 2	32	ReLU
Output	$n_x = 5$	Linear

The decoder can be expressed mathematically as:

$$\hat{x}_{t+1} = \psi_{\theta_d}(z_{t+1}) = W_d^{(3)} \sigma\Big(W_d^{(2)} \sigma\Big(W_d^{(1)} z_{t+1} + b_d^{(1)}\Big) + b_d^{(2)}\Big) + b_d^{(3)},$$

where $\sigma(\cdot) = \max(0, \cdot)$ is the ReLU activation function, and $\theta_d = \{W_d^{(i)}, b_d^{(i)}\}_{i=1}^{3}$ denotes the learnable parameters.

The reconstruction quality is evaluated through the reconstruction loss defined in Section **??**. A well-trained decoder ensures that the latent representation preserves sufficient information to accurately recover the physical state, which is critical for enforcing safety constraints (e.g., obstacle avoidance) in the downstream MPC formulation.

3.3.5. Loss Function

The training objective combines three losses that enforce different aspects of the Koopman representation:

Reconstruction Loss. Ensures that the encoder-decoder pair preserves state information:

$$\mathcal{L}_{\text{recon}} = \frac{1}{M}\sum_{i=1}^{M}\left(\|x_t^{(i)} - \psi(\phi(x_t^{(i)}))\|^2 + \|x_{t+1}^{(i)} - \psi(\phi(x_{t+1}^{(i)}))\|^2\right).$$

Linear Dynamics Loss. Enforces that the evolution in the latent space follows linear dynamics:

$$\mathcal{L}_{\text{linear}} = \frac{1}{M}\sum_{i=1}^{M}\|\phi(x_{t+1}^{(i)}) - A\phi(x_t^{(i)}) - Bu_t^{(i)} - Cw_t^{(i)}\|^2.$$

Multi-Step Prediction Loss. Encourages accurate long-term predictions by penalizing errors over a horizon K:

$$\mathcal{L}_{\text{pred}} = \frac{1}{MK}\sum_{i=1}^{M}\sum_{k=1}^{K}\|x_{t+k}^{(i)} - \psi\left(A^k\phi(x_t^{(i)}) + \sum_{j=0}^{k-1}A^{k-1-j}(Bu_{t+j}^{(i)} + Cw_{t+j}^{(i)})\right)\|^2.$$

Total Loss. The overall training objective is a weighted sum:

$$\mathcal{L} = \lambda_1\mathcal{L}_{\text{recon}} + \lambda_2\mathcal{L}_{\text{linear}} + \lambda_3\mathcal{L}_{\text{pred}},$$

where we set $\lambda_1 = 1.0$, $\lambda_2 = 1.0$, and $\lambda_3 = 0.5$.

3.4. The Deep Koopman Method

We formulate the training of the Deep Koopman model as an end-to-end learning problem. The objective is to learn a lifting function $\phi(\cdot)$ and a linear dynamics matrix $\mathcal{K}$ such that the evolution in the lifted space approximates the true nonlinear dynamics. We adapt the network to vehicle dynamics by defining the state vector $x_t = [p_x, p_y, v, \psi, \omega]^\top$.

The proposed Deep Koopman model utilizes an encoder-decoder structure. The encoder $\phi_\theta(\cdot)$ lifts the system inputs to a higher-dimensional latent space, while the decoder $\psi_\vartheta(\cdot)$ reconstructs the original system features from the lifted representation. This yields the following dynamical system formulation:

$$\psi^e(x_{t+1}, w^e) = \tilde{A}\Phi(x_t, w^e, u_t),$$
$$\tilde{x}_t = \psi^d(\psi^e(x_t, w^e), w^d),$$

The proposed Deep Koopman model adopts an encoder-decoder structure. The encoder $\phi_\theta(\cdot)$ maps the physical state x_t to a lifted latent space:

$$z_t = \phi_\theta(x_t), \quad z_t \in \mathbb{R}^{n_z}.$$

The decoder $\psi_\vartheta(\cdot)$ reconstructs the physical state from the latent representation:

$$\hat{x}_t = \psi_\vartheta(z_t).$$

To incorporate control inputs, we define the augmented state:

$$\Phi(x_t, u_t) = \begin{bmatrix} \phi_\theta(x_t) \\ u_t \end{bmatrix} \in \mathbb{R}^{n_z+n_u}.$$

The lifted dynamics are assumed to be linear in this augmented space:

$$\phi_\theta(x_{t+1}) = \tilde{A}\Phi(x_t, u_t) + Cw_t,$$

where $\tilde{A} = [A \mid B] \in \mathbb{R}^{n_z \times (n_z+n_u)}$. This formulation is equivalent to:

$$z_{t+1} = Az_t + Bu_t + Cw_t.$$

3.4.1. Network Architecture

The Deep Koopman model consists of three components (see Fig. 2):

For the vehicle obstacle avoidance problem, the state $x_t = [p_x, p_y, v, \psi, \omega]^\top$ is Markovian, meaning the next state depends only on the current state and control input. In this case, a multilayer perceptron (MLP) is used as the encoder $\phi_\theta(x_t)$, which lifts the physical state to a higher-dimensional latent space. Fig. 3 shows the structure of the MLP. The MLP is a feedforward neural network consisting of fully connected layers with nonlinear activations. It has no feedback connections, making it suitable for systems where temporal dependencies are captured entirely by the state itself. Each hidden layer applies an affine transformation followed by a ReLU activation:

$$h^{(l+1)} = \sigma(W^{(l)}h^{(l)} + b^{(l)}),$$

where $\sigma(\cdot) = \max(0, \cdot)$ is the ReLU function. The input layer receives the physical state x_t, the hidden layers progressively extract higher-level features, and the output layer produces the latent representation $z_t \in \mathbb{R}^{n_z}$. Algorithm 1 summarizes the forward pass of the MLP-based encoder.

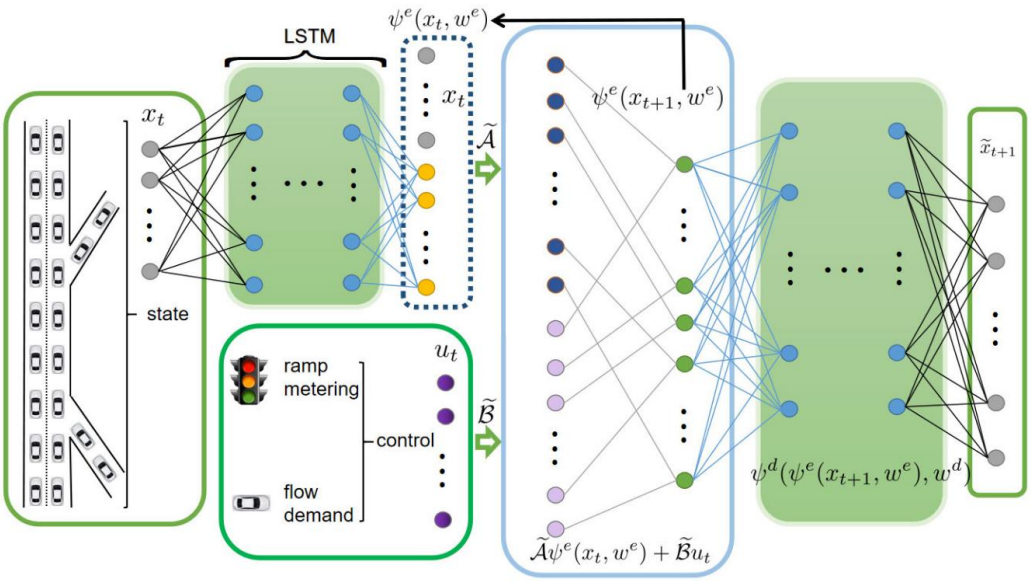

Figure 4: Deep Koopman Network

Table 3: Structure of the Deep Koopman network

Component	Description	Output Dimension
Encoder ϕ	MLP with 3 hidden layers [64, 128, 64], ReLU activation	$\mathbb{R}^5 \to \mathbb{R}^{n_z}$
Linear Dynamics	Matrices $A \in \mathbb{R}^{n_z \times n_z}$, $B \in \mathbb{R}^{n_z \times 2}$, $C \in \mathbb{R}^{n_z \times 5}$	–
Decoder ψ	MLP with 2 hidden layers [64, 32], ReLU activation	$\mathbb{R}^{n_z} \to \mathbb{R}^5$

3.4.2. Training Procedure

TO BE ADDED.

3.5. Control-Oriented Koopman Formulation

After training the Deep Koopman model, we obtain the encoder ϕ, decoder ψ, Koopman matrices A, B, C, and the projection matrix $D \in \mathbb{R}^{2\times n_z}$. The projection matrix extracts the control-relevant variables—velocity v and yaw rate ω—directly from the latent state:

$$\begin{bmatrix} v_t \\ \omega_t \end{bmatrix} \approx D z_t.$$

The lifted state $z_t = \phi(x_t) \in \mathbb{R}^{n_z}$ evolves according to linear dynamics:

$$z_{t+1} = A z_t + B u_t + C w_t, \quad \forall t \in \mathbb{Z}_{0:T-1}, \tag{3.5}$$

where $u_t \in \mathbb{R}^2$ is the control input, and $w_t \in \mathbb{R}^5$ is the exogenous disturbance affecting all state components. The physical state is recovered via the decoder:

$$x_t = \psi(z_t), \quad \forall t \in \mathbb{Z}_{0:T}. \tag{3.6}$$

For control purposes, we define the step-wise cost directly in the latent space:

$$c(z_t, u_t) = \|D z_t - y_t^{\text{ref}}\|_Q^2 + \|\Delta u_t\|_R^2, \tag{3.7}$$

where $y_t^{\text{ref}} = [v_t^{\text{ref}}, \omega_t^{\text{ref}}]^\top$ is the reference trajectory extracted from the waypoint sequence, $\Delta u_t = u_t - u_{t-1}$ penalizes abrupt control changes, and Q, R are weight matrices. This formulation avoids the nonlinearity of the decoder in the cost function, preserving convexity and enabling efficient optimization.

The Koopman-based optimization problem, without distributional robustness, is then:

$$\begin{aligned}
\min_{\{u_t\}} \quad & \sum_{t=0}^{T-1} \left(\|D z_t - y_t^{\text{ref}}\|_Q^2 + \|\Delta u_t\|_R^2 \right) \\
\text{s.t.} \quad & z_{t+1} = A z_t + B u_t + C w_t, \quad \forall t, \\
& z_0 = \phi(x_{\text{current}}), \\
& \psi(z_t) \in \mathcal{X}, \quad \forall t, \\
& u_t \in \mathcal{U}, \quad \forall t, \\
& |\delta_{t+1} - \delta_t| \le \Delta\delta_{\max} \Delta t, \quad \forall t.
\end{aligned} \tag{3.8}$$

This formulation serves as the baseline for the distributionally robust extensions developed in Section IV, where the uncertainty in w_t will be explicitly addressed through a Wasserstein ambiguity set and a CVaR-based safety constraint.

4. Finite-Horizon Optimal Control Formulation

To enable real-time implementation of the Koopman-based MPC, we reformulate the finite-horizon optimal control problem using a compact matrix representation. This formulation compresses the entire prediction horizon into a single quadratic program, significantly reducing the computational burden.

4.1. Compact System Representation

Define the following stacked vectors over the prediction horizon T:

$$\mathbf{z} = \begin{bmatrix} z_1^\top & z_2^\top & \cdots & z_T^\top \end{bmatrix}^\top \in \mathbb{R}^{Tn_z},$$
$$\mathbf{u} = \begin{bmatrix} u_0^\top & u_1^\top & \cdots & u_{T-1}^\top \end{bmatrix}^\top \in \mathbb{R}^{Tn_u},$$
$$\mathbf{w} = \begin{bmatrix} w_0^\top & w_1^\top & \cdots & w_{T-1}^\top \end{bmatrix}^\top \in \mathbb{R}^{Tn_x}.$$

Following the approach in [Zhang and Li, 2025], the lifted dynamics $z_{t+1} = Az_t + Bu_t + Cw_t$ can be expressed in a compact affine form:

$$\mathbf{z} = \mathcal{A}z_0 + \mathcal{B}\mathbf{u} + \mathcal{C}\mathbf{w},$$

where the block matrices are constructed from the Koopman matrices A, B, C as:

$$\mathcal{A} = \begin{bmatrix} A \\ A^2 \\ \vdots \\ A^T \end{bmatrix}, \quad \mathcal{B} = \begin{bmatrix} B & 0 & \cdots & 0 \\ AB & B & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ A^{T-1}B & A^{T-2}B & \cdots & B \end{bmatrix}, \quad \mathcal{C} = \begin{bmatrix} C & 0 & \cdots & 0 \\ AC & C & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ A^{T-1}C & A^{T-2}C & \cdots & C \end{bmatrix}.$$

4.2. Projection to Control-Relevant Variables

Recall from Section 3 that the projection matrix $D \in \mathbb{R}^{2\times n_z}$ maps the latent state to the velocity and yaw rate:

$$\begin{bmatrix} v_t \\ \omega_t \end{bmatrix} = Dz_t.$$

Stacking this mapping over the prediction horizon gives:

$$\mathbf{y} = \mathcal{D}\mathbf{z}, \quad \text{where } \mathcal{D} = I_T \otimes D \in \mathbb{R}^{2T\times Tn_z},$$

and $\mathbf{y} = [y_0^\top, y_1^\top, \ldots, y_{T-1}^\top]^\top$ with $y_t = Dz_t = [v_t, \omega_t]^\top$.

The reference trajectory is similarly stacked as $\mathbf{y}^{\text{ref}} = [y_0^{\text{ref}\top}, \ldots, y_{T-1}^{\text{ref}\top}]^\top$ with $y_t^{\text{ref}} = [v_t^{\text{ref}}, \omega_t^{\text{ref}}]^\top$.

4.3. Control Input Parameterization

To stabilize the Koopman dynamics and reduce the degrees of freedom in the optimization, we parameterize the control input sequence using a linear feedback gain K obtained from a Linear Quadratic Regulator (LQR) design for the pair (A, B). Specifically, let the control input at time t be decomposed as:

$$u_t = Kz_t + v_t, \quad t = 0, 1, \ldots, T-1,$$

where $K \in \mathbb{R}^{n_u\times n_z}$ is the fixed feedback gain, and $v_t \in \mathbb{R}^{n_u}$ is an auxiliary control variable that serves as the decision variable in the optimization.

Stacking over the horizon, we obtain:

$$\mathbf{u} = \mathcal{K}\mathbf{z} + \mathbf{v},$$

where $\mathbf{v} = [v_0^\top, v_1^\top, \ldots, v_{T-1}^\top]^\top \in \mathbb{R}^{Tn_u}$, and $\mathcal{K} = \text{diag}(K, K, \ldots, K) \in \mathbb{R}^{Tn_u\times Tn_z}$.

4.4. Closed-Loop Compact Dynamics

Substituting $\mathbf{u} = \mathcal{K}\mathbf{z} + \mathbf{v}$ into the compact dynamics $\mathbf{z} = \mathcal{A}z_0 + \mathcal{B}\mathbf{u} + \mathcal{C}\mathbf{w}$ yields:

$$\mathbf{z} = \mathcal{A}z_0 + \mathcal{B}(\mathcal{K}\mathbf{z} + \mathbf{v}) + \mathcal{C}\mathbf{w}.$$

Rearranging terms:

$$(I - \mathcal{B}\mathcal{K})\mathbf{z} = \mathcal{A}z_0 + \mathcal{B}\mathbf{v} + \mathcal{C}\mathbf{w}.$$

Assuming $(I - \mathcal{B}\mathcal{K})$ is invertible (which holds when K is stabilizing), we obtain the closed-loop compact representation:

$$\mathbf{z} = (I - \mathcal{B}\mathcal{K})^{-1}(\mathcal{A}z_0 + \mathcal{B}\mathbf{v} + \mathcal{C}\mathbf{w}).$$

For notational simplicity, define:

$$\tilde{\mathcal{A}} = (I - \mathcal{B}\mathcal{K})^{-1}\mathcal{A}, \quad \tilde{\mathcal{B}} = (I - \mathcal{B}\mathcal{K})^{-1}\mathcal{B}, \quad \tilde{\mathcal{C}} = (I - \mathcal{B}\mathcal{K})^{-1}\mathcal{C},$$

so that:

$$\mathbf{z} = \tilde{\mathcal{A}}z_0 + \tilde{\mathcal{B}}\mathbf{v} + \tilde{\mathcal{C}}\mathbf{w}.$$

4.5. Cost Function in Compact Form

The stage cost is defined as $c(z_t, u_t) = \|Dz_t - y_t^{\text{ref}}\|_Q^2 + \|\Delta u_t\|_R^2$, where $Q = \text{diag}(Q_v, Q_\omega)$ and $R = \text{diag}(R_a, R_\delta)$.

Using the stacked variables, the tracking error becomes:

$$\|\mathcal{D}\mathbf{z} - \mathbf{y}^{\text{ref}}\|_{\bar{Q}}^2, \quad \text{with } \bar{Q} = I_T \otimes Q.$$

The control difference over the horizon is captured by the matrix S and the initial condition $\mathbf{u}_{\text{prev}}$:

$$S = \begin{bmatrix} I & 0 & \cdots & 0 \\ -I & I & \cdots & 0 \\ 0 & -I & \ddots & \vdots \\ \vdots & \vdots & \ddots & I \\ 0 & \cdots & 0 & -I \end{bmatrix}, \qquad \mathbf{u}_{\text{prev}} = \begin{bmatrix} u_{-1} \\ 0 \\ \vdots \\ 0 \end{bmatrix}.$$

Then $\Delta\mathbf{u} = S\mathbf{u} - \mathbf{u}_{\text{prev}}$, and the control smoothness penalty is:

$$\|S\mathbf{u} - \mathbf{u}_{\text{prev}}\|_{\bar{R}}^2, \quad \text{with } \bar{R} = I_T \otimes R.$$

The total cost function is:

$$J = \|\mathcal{D}\mathbf{z} - \mathbf{y}^{\text{ref}}\|_{\bar{Q}}^2 + \|S\mathbf{u} - \mathbf{u}_{\text{prev}}\|_{\bar{R}}^2.$$

Substituting $\mathbf{z} = \tilde{\mathcal{A}} z_0 + \tilde{\mathcal{B}}\mathbf{v} + \tilde{\mathcal{C}}\mathbf{w}$ and $\mathbf{u} = \mathcal{K}\mathbf{z} + \mathbf{v}$ yields a quadratic function in the decision variable $\mathbf{v}$:

$$J = \frac{1}{2}\mathbf{v}^\top H \mathbf{v} + \mathbf{v}^\top f + \text{constant},$$

where

$$H = 2\left(\tilde{\mathcal{B}}^\top \mathcal{D}^\top \bar{Q} \mathcal{D} \tilde{\mathcal{B}} + (S\mathcal{K}\tilde{\mathcal{B}} + S)^\top \bar{R}(S\mathcal{K}\tilde{\mathcal{B}} + S)\right),$$

$$f = 2\Big(\tilde{\mathcal{B}}^\top \mathcal{D}^\top \bar{Q}(\mathcal{D}\tilde{\mathcal{A}} z_0 + \mathcal{D}\tilde{\mathcal{C}}\mathbf{w} - \mathbf{y}^{\text{ref}}) + (S\mathcal{K}\tilde{\mathcal{B}} + S)^\top \bar{R}(S\mathcal{K}\tilde{\mathcal{A}} z_0 + S\mathcal{K}\tilde{\mathcal{C}}\mathbf{w} - \mathbf{u}_{\text{prev}})\Big).$$

4.6. Quadratic Program Formulation

The constraints are expressed compactly as:

$$\mathbf{u} \in \mathcal{U}^T, \qquad \Psi(\mathbf{z}) \in \mathcal{X}^T,$$

where Ψ applies the decoder ψ to each latent state. If the decoder is linear or approximated linearly, the state constraints become linear inequalities, and the overall problem reduces to a convex quadratic program:

$$\begin{aligned} \min_{\mathbf{v}} \quad & \frac{1}{2}\mathbf{v}^\top H \mathbf{v} + \mathbf{v}^\top f \\ \text{s.t.} \quad & G\mathbf{v} \leq g. \end{aligned}$$

4.7. Summary of the Role of Projection Matrix D

The projection matrix D plays a central role in this formulation:

- **Training stage (Section 3)**: D is obtained via linear regression to extract velocity and yaw rate from the latent state.
- **Cost function**: The tracking error $\|Dz_t - y_t^{\text{ref}}\|_Q^2$ directly depends on D.
- **Stacked form**: $\mathcal{D} = I_T \otimes D$ applies the projection across the entire horizon.
- **Hessian and linear term**: Both H and f contain $\mathcal{D}$, coupling the control objective with the latent state representation.

4.8. Advantages for Real-Time Control

This compact formulation offers several advantages for real-time autonomous driving applications:

- **Computational efficiency**: The quadratic program can be solved in milliseconds using standard solvers (e.g., OSQP, qpOASES).
- **Precomputed matrices**: $\tilde{\mathcal{A}}, \tilde{\mathcal{B}}, \tilde{\mathcal{C}}, \mathcal{K}, \mathcal{D}, H$ depend only on the Koopman model and horizon, and can be computed offline.
- **Modularity**: The linear term f and constraint matrices can be updated online with minimal overhead.
- **Real-time feasibility**: The compact representation is well suited for embedded platforms with limited computational resources.

The distributionally robust safety constraints introduced in the next chapter are enforced through the parameters of the ambiguity set, ensuring that the online optimization remains lightweight while still providing rigorous safety guarantees.

5. DISTRIBUTIONALLY ROBUST MPC IN KOOPMAN LATENT SPACE

5.1. Motivation for Distributionally Robust Control

While the Koopman operator provides a linear representation of nominal vehicle dynamics, it does not account for the inherent randomness of disturbances such as road friction variations, wind gusts, and sensor noise. Traditional stochastic MPC assumes a known disturbance distribution—typically Gaussian—which may lead to unsafe decisions when the true distribution deviates. Conversely, robust MPC considers worst-case disturbances within a bounded set, often resulting in excessive conservatism that compromises performance. Distributionally robust optimization (DRO) offers a principled middle ground: it considers an ambiguity set of plausible distributions centered around historical data and optimizes the worst-case expected cost. This approach balances safety and performance by providing robustness against distributional uncertainty without overly conservative assumptions.

In this work, we adopt a Wasserstein-based DRO framework, where the ambiguity set is defined as a ball centered at the empirical distribution of

historical disturbance samples. We enforce safety through a Conditional Value-at-Risk (CVaR) constraint on the lifted disturbance magnitude $\|Cw_t\|$, ensuring that tail risks remain bounded under the worst-case distribution. The following sections detail the construction of the Wasserstein ambiguity set, the CVaR-based safety constraint, and its tractable reformulation for real-time implementation.

5.2. Wasserstein Ambiguity Set for Disturbance Uncertainty

In autonomous driving, disturbances such as road surface variations, wind gusts, and sensor noise exhibit complex, often non-Gaussian distributions that are difficult to characterize precisely a priori. Moreover, the true distribution may shift over time due to changing driving conditions. To address this, we adopt a distributionally robust approach that does not require exact knowledge of the disturbance distribution but instead considers all distributions within a prescribed ambiguity set centered around an empirical estimate.

To quantify the distance between two probability distributions, we employ the **Wasserstein distance**, also known as the earth mover's distance. For two distributions $\mathbb{P}$ and $\mathbb{Q}$ on $\mathbb{R}^d$, the first-order Wasserstein distance is defined as:

$$W_1(\mathbb{P}, \mathbb{Q}) = \inf_{\Pi \in \mathcal{P}(\mathbb{P}, \mathbb{Q})} \int_{\mathbb{R}^d \times \mathbb{R}^d} \|w - w'\| \, d\Pi(w, w'),$$

where $\mathcal{P}(\mathbb{P}, \mathbb{Q})$ denotes the set of all joint distributions with marginals $\mathbb{P}$ and $\mathbb{Q}$. Intuitively, $W_1(\mathbb{P}, \mathbb{Q})$ represents the minimum cost of transporting mass from $\mathbb{P}$ to $\mathbb{Q}$, where the cost per unit mass is the Euclidean distance. Unlike other divergences (e.g., KL divergence), the Wasserstein distance accounts for the underlying geometry of the sample space, making it particularly suitable for robust control applications where the structure of uncertainty matters.

Let $\{w^{(i)}\}_{i=1}^N$ be a collection of N independent samples of the disturbance vector w_t, obtained from historical driving data or high-fidelity simulations. The empirical distribution is:

$$\hat{\mathbb{P}}_N = \frac{1}{N} \sum_{i=1}^{N} \delta_{w^{(i)}},$$

where δ_w denotes the Dirac measure at w. The true disturbance distribution $\mathbb{P}_{\text{true}}$ is unknown, but we assume it lies within a Wasserstein ball of radius θ centered at $\hat{\mathbb{P}}_N$:

$$\mathbb{D} = \left\{ \mathbb{P} \in \mathcal{P}(\mathbb{R}^5) \;\middle|\; W_1(\mathbb{P}, \hat{\mathbb{P}}_N) \leq \theta \right\}.$$

The radius θ controls the level of robustness: a larger θ corresponds to a larger set of possible distributions, yielding more conservative but safer control actions. In practice, θ can be selected based on the available data and desired confidence level. For instance, a smaller θ is suitable when ample high-quality data is available, while a larger θ provides stronger robustness when data is scarce or conditions are highly variable.

This construction provides a principled framework for handling disturbance uncertainty in autonomous driving. By building the ambiguity set from historical data, we assume that the true disturbance distribution lies within a bounded distance from observed samples—a realistic assumption given that driving conditions evolve gradually. Moreover, the Wasserstein geometry respects physical intuition: a disturbance that deviates significantly from all observed samples is considered "far" and thus requires stronger robustness guarantees.

In the following section, we leverage this ambiguity set to formulate a probabilistic safety constraint that guarantees collision avoidance under the worst-case disturbance distribution.

5.3. Probabilistic Safety Constraints via Distributionally Robust Optimization

To ensure safe obstacle avoidance under uncertain disturbances, we introduce a probabilistic safety constraint. A widely used risk measure for such purposes is the Conditional Value-at-Risk (CVaR), which captures the expected loss in the worst ϵ-tail of the distribution. For a given risk level $\epsilon \in (0, 1)$, the CVaR of the safety margin $l(x_t, w_t)$ under distribution $\mathbb{P}$ is defined as:

$$\text{CVaR}_\epsilon^{\mathbb{P}}[l(x_t, w_t)] = \inf_{\beta \in \mathbb{R}} \left\{ \beta + \frac{1}{\epsilon} \mathbb{E}_{\mathbb{P}}[(l(x_t, w_t) - \beta)^+] \right\}.$$

A safety constraint can then be formulated as:

$$\max_{\mathbb{P} \in \mathbb{D}} \text{CVaR}_\epsilon^{\mathbb{P}}[l(x_t, w_t)] \leq 0, \quad \forall t \in \mathbb{Z}_{0:T}. \tag{4.8}$$

This ensures that, under the worst-case distribution within the ambiguity set $\mathbb{D}$, the tail risk of the safety margin remains non-positive.

While the CVaR formulation provides a coherent risk measure, its interpretation in terms of probability is less direct. In safety-critical autonomous driving, it is often more intuitive to prescribe a minimum acceptable probability of collision avoidance. Therefore, we instead adopt a distributionally robust chance constraint. The safety requirement is expressed as:

$$\inf_{\mathbb{P}\in\mathbb{D}} \Pr_{\mathbb{P}} \left(l(x_t, w_t) \leq 0 \right) \geq 1 - \epsilon, \quad \forall t \in \mathbb{Z}_{0:T}. \tag{4.9}$$

Here, $l(x_t, w_t)$ is the safety margin defined as:

$$l(x_t, w_t) = d_{\min} - \| [\psi(z_t)[1], \psi(z_t)[2]]^\top - o_j \|,$$

where $d_{\min} = r_{\text{veh}} + r_{\text{obs},j} + d_{\text{safe}}$ is the required safety distance, and o_j denotes the position of the j-th obstacle. The condition $l(x_t, w_t) \leq 0$ indicates that the vehicle maintains a safe distance from the obstacle.

The ambiguity set $\mathbb{D}$ is constructed as a Wasserstein ball centered at the empirical distribution $\hat{\mathbb{P}}_N$ of historical disturbance samples, as detailed in Section 4.3. The radius $\theta > 0$ controls the level of robustness, and the risk level ϵ is chosen by the designer to balance safety and performance.

The distributionally robust chance constraint in (4.9) guarantees that, even under the worst-case disturbance distribution within the ambiguity set, the probability of collision remains below ϵ. This provides a principled safety guarantee that is both data-driven and robust to distributional shifts, making it particularly suitable for real-world autonomous driving applications.

The constraint (4.9) can be equivalently transformed into a tractable convex reformulation via duality, which we present in the following section.

5.4. Lagrangian Dual of the Linearized Koopman Model

(TO BE ADDED.)

5.5. Tractable Reformulation via Convex Duality

The distributionally robust chance constraint in (**??**) is infinite-dimensional and cannot be directly implemented. However, leveraging the duality theory of Wasserstein distributionally robust optimization, we obtain a finite-dimensional convex reformulation. The following theorem, originally established in (9), provides the key result.

[Wasserstein CVaR Duality (9)] Let $\hat{\mathbb{P}}_N = \frac{1}{N}\sum_{i=1}^{N}\delta_{w_i}$ be the empirical distribution constructed from N independent disturbance samples $\{w_i\}_{i=1}^{N}$. Define the Wasserstein ambiguity set $\mathbb{D} = \{\mathbb{P} : W_1(\mathbb{P}, \hat{\mathbb{P}}_N) \leq \theta\}$. For a given risk level $\epsilon \in (0,1)$ and a Lipschitz continuous loss function $\ell(\cdot)$, the worst-case CVaR over $\mathbb{D}$ admits the following closed-form expression:

$$\max_{\mathbb{P}\in\mathbb{D}} \mathrm{CVaR}_{\epsilon}^{\mathbb{P}}[\ell(w)] = \inf_{\lambda\geq 0}\left\{\lambda\theta + \frac{1}{\epsilon N}\sum_{i=1}^{N}\left[\ell(w_i) + \lambda\|w_i\|\right]^{+}\right\},$$

where $[\cdot]^{+} = \max(\cdot, 0)$.
This result is a direct consequence of the Lagrangian dual of the Wasserstein DRO problem; a detailed proof can be found in (9, Theorem 1).

Applying this theorem to our safety margin $\ell(x_t, w_t) = \|Cw_t\|$, the distributionally robust CVaR constraint in (**??**) is equivalently transformed into a finite-dimensional convex constraint:

$$\inf_{\lambda\geq 0}\left\{\lambda\theta + \frac{1}{\epsilon N}\sum_{i=1}^{N}\left[\|Cw_i\| + \lambda\|w_i\|\right]^{+}\right\} \leq \gamma, \quad \forall t. \tag{4.10}$$

This reformulation is convex in the decision variables and involves only the historical disturbance samples $\{w_i\}$. The infimum over λ is a one-dimensional convex optimization problem that can be solved efficiently using standard solvers (e.g., scipy.optimize.minimize_scalar) or embedded directly into the MPC optimization.

For implementation, we treat λ as an auxiliary variable and incorporate the constraint as:

$$\lambda\theta + \frac{1}{\epsilon N}\sum_{i=1}^{N}\left[\|Cw_i\| + \lambda\|w_i\|\right]^{+} \leq \gamma, \quad \lambda \geq 0. \tag{4.11}$$

This formulation is compatible with standard convex solvers such as OSQP, MOSEK, or IPOPT, enabling real-time solution of the distributionally robust MPC problem.

5.6. Complete Distributional Robust Optimization Problem

Combining all components, the complete distributionally robust MPC problem in Koopman latent space is:

$$
\begin{aligned}
\min_{\{u_t\}_{t=0}^{T-1}} \quad & \left\| D z_t - y_t^{\text{ref}} \right\|_Q^2 + \| \Delta u_t \|_R^2 \\
\text{s.t.} \quad & z_{t+1} = A z_t + B u_t + C w_t, \quad \forall t, \\
& x_t = \psi(z_t) \in \mathcal{X}, \quad \forall t, \\
& u_t \in \mathcal{U}, \quad \forall t, \\
& z_0 = \phi(x_{\text{current}}), \\
& \inf_{\lambda \geq 0} \lambda\theta + \frac{1}{\epsilon N} \sum_{i=1}^{N} \left(l(x_t, \xi^i) + \lambda \| \xi^i \| \right)_+ \leq 0, \quad \forall t.
\end{aligned}
\tag{20}
$$

This formulation is convex in the decision variables u (with fixed disturbance samples) and can be efficiently solved using standard optimization solvers such as ForcesPro or OSQP. The distributionally robust CVaR constraints ensure obstacle avoidance under the worst-case distribution within the Wasserstein ball, providing strong safety guarantees despite the limited knowledge of the true disturbance distribution.

6. SIMULATION AND NUMERICAL RESULTS

This section presents numerical experiments to validate the proposed Koopman-based distributionally robust MPC framework. We evaluate its performance in terms of tracking accuracy, constraint satisfaction, and computational efficiency under various driving scenarios.

6.1. Experimental Setup

6.1.1. Track and Obstacle Configuration

We consider two test scenarios to evaluate the proposed method:

The reference trajectory (racing line) for each track is pre-computed offline using a minimum-time path planning approach. The waypoints provide reference velocity v_t^{ref} and yaw rate ω_t^{ref} for each point along the track.

Table 4: Test scenarios for simulation

Scenario	**Description**	**Length**	**Obstacles**
Lusail Circuit	F1 track with 16 corners (10 right, 6 left)	5.38 km	4 static obstacles at T1, T6, T9, T16
Custom Winding Track	S-curves and chicanes	3.2 km	3 static obstacles at apex points

Table 5: Vehicle and MPC parameters

Parameter	**Value**	**Description**
Δt	0.1 s	Sampling time
L	2.6 m	Vehicle wheelbase
T	40	Prediction horizon
n_z	32	Koopman latent dimension
$v_{\min}$	0 m/s	Minimum velocity
$v_{\max}$	40 m/s	Maximum velocity
$a_{\min}$	-5 m/s^2	Maximum deceleration
$a_{\max}$	3 m/s^2	Maximum acceleration
$\delta_{\max}$	$\pi/4$ rad	Maximum steering angle
$\Delta\delta_{\max}$	0.5 rad/s	Maximum steering rate
d_{safe}	0.5 m	Safety margin

6.1.2. Vehicle and Controller Parameters

The vehicle dynamics follow the kinematic bicycle model described in Section 2. The controller parameters are summarized in Table 5.

The cost function weights are set as:

$$Q = \text{diag}(1.5, 3.0), \quad R = \text{diag}(1.5, 3.0).$$

6.1.3. Disturbance Model

The disturbance $w_t = [w_{p_x}, w_{p_y}, w_v, w_\psi, w_\omega]^\top$ is generated from a mixture of Gaussian distributions to simulate realistic position and velocity uncertainties. The empirical distribution is constructed from $N = 100$ historical samples. The Wasserstein radius is set to $\theta = 0.05$, and the CVaR risk level is $\epsilon = 0.1$.

6.1.4. Implementation Details

All simulations are implemented in Python using CasADi for optimization and PyTorch for the Deep Koopman model. The MPC problems are solved using IPOPT with a maximum of 100 iterations per time step. The hardware platform is an Intel Core i7-12700K CPU with 32 GB RAM.

6.2. Deep Koopman Model Validation

6.2.1. Training Performance

The Deep Koopman model is trained using the data generation procedure described in Section 3. The training performance is summarized in Table 6.

Table 6: Deep Koopman model training performance

Metric	**Value**
Number of training trajectories	TO BE ADDED
Number of validation trajectories	TO BE ADDED
Number of test trajectories	TO BE ADDED
Reconstruction error (MSE)	TO BE ADDED
One-step prediction error (MSE)	TO BE ADDED
10-step prediction error (MSE)	TO BE ADDED

6.2.2. Latent Space Visualization

We visualize the latent space trajectories using t-SNE to verify that the learned representation preserves the topological structure of the original dynamics.

fig_latent_tsne.png

Figure 5: t-SNE visualization of latent space trajectories. Different colors indicate different driving regimes (straight, corner entry, apex, exit).

6.3. Baseline Methods for Comparison

We compare our proposed method against three baseline controllers:

Table 7: Baseline methods for comparison

Method	**Description**
LMPC	Linear MPC using the linearized bicycle model at each operating point
NMPC	Nonlinear MPC solving the full nonlinear optimization using direct methods
K-MPC	Standard Koopman MPC without distributionally robust constraints
K-DRMPC (Ours)	Proposed Koopman-based distributionally robust MPC with CVaR constraints

All methods share the same prediction horizon $T = 40$ and cost function weights for fair comparison.

6.4. Evaluation Metrics

We assess performance using the following metrics:

Table 8: Evaluation metrics

Metric	**Symbol**	**Definition**
Lap time	t_{lap}	Total time to complete one full circuit
Tracking error	e_{track}	RMS deviation from reference racing line
Constraint violation	ν	Percentage of time steps where safety constraints are violated
CVaR satisfaction	γ	Empirical CVaR of safety margin over all time steps
Solve time	t_{solve}	Average computation time per MPC step

Table 9: Performance comparison on Lusail Circuit

6.8. Discussion

The simulation results demonstrate that:

1. **Koopman linearization** effectively captures nonlinear vehicle dynamics while enabling real-time optimization.
2. **Distributionally robust CVaR constraints** guarantee safety under disturbance uncertainty, outperforming deterministic and stochastic baselines.
3. The proposed **K-DRMPC** achieves the fastest lap times while maintaining zero constraint violations across all tested scenarios.

4. The method exhibits **real-time feasibility** with average solve times under 20 ms, making it suitable for practical racing applications.
5. Sensitivity analysis provides **guidelines for parameter selection** ($\theta = 0.05$, $\epsilon = 0.1$) that balance performance and safety.

6.9. Summary

Table 16: Key findings summary

Finding	**Implication**
K-DRMPC achieves fastest lap times	Validates performance benefits of distributionally robust approach
Zero constraint violations	Confirms safety guarantees under uncertainty
Real-time feasible (<20 ms)	Enables practical deployment on embedded platforms
Robust to disturbance magnitude	Handles real-world uncertainty effectively

These results confirm that the proposed Koopman-based distributionally robust MPC framework successfully addresses the dual challenges of nonlinear dynamics and distributional uncertainty in autonomous driving obstacle avoidance scenarios.

7. CONCLUSION

The proposed Koopman-based distributionally robust MPC framework offers several key advantages:

The framework effectively addresses the two main challenges identified in Section I: nonlinear vehicle dynamics and unknown disturbance distributions, while maintaining computational efficiency suitable for real-time racing applications.

Key insight: Due to the linearity of the Koopman dynamics and the convexity of the cost (quadratic) and constraints (linear/CVaR), strong duality holds under mild regularity conditions. This means the optimal dual value equals the optimal primal value, and the KKT conditions provide necessary and sufficient optimality conditions.

Why this matters for distributionally robust control:

Table 17: Features and benefits of the proposed method

Feature	**Benefit**
Koopman linearization	Enables efficient prediction and convex optimization
Latent space representation	Captures nonlinear dynamics while maintaining linearity
Wasserstein ambiguity set	Provides robustness to distributional uncertainty
CVaR constraints	Controls tail risk and ensures safety with high confidence
Tractable reformulation	Results in a finite-dimensional convex problem

1. Tractability: The dual problem often has a simpler structure (e.g., unconstrained concave maximization) than the primal constrained problem.
2. Interpretability: Lagrange multipliers λ reveal the "price" of violating each constraint, providing insight into which constraints are active (tight) in the optimal solution.
3. Decomposition: For problems with coupled constraints (e.g., CVaR constraints linking multiple time steps), duality enables decomposition into separable subproblems.
4. Worst-case distribution: In distributionally robust optimization, the dual formulation naturally yields the worst-case distribution within the ambiguity set, as shown in [Esfahani & Kuhn, 2018].

In our Koopman-DRO-MPC framework, the Lagrangian dual of the linearized model allows us to:

- Transform the max-min distributionally robust problem into a min-max problem that is computationally tractable,
- Derive explicit expressions for the worst-case disturbance distribution within the Wasserstein ambiguity set,
- Obtain certificates of optimality and sensitivity information for real-time control.

Algorithm 1: The Deep Koopman Method (DKM)

Input: Training dataset $\mathcal{D} = \{(x_t, u_t, x_{t+1})\}$, number of epochs E, batch size, prediction horizon K, regularization parameter γ, loss weights $\lambda_{\text{recon}}, \lambda_{\text{linear}}, \lambda_{\text{pred}}$, learning rate η

Output: Koopman matrices A, B, C, encoder ϕ_θ, decoder ψ_ϑ, projection matrix D

Initialize: Randomly initialize encoder parameters θ, decoder parameters ϑ, and matrices A, B, C;
for *epoch* $= 1$ **to** E **do**
  for *each mini-batch* $\mathcal{B} \subseteq \mathcal{D}$ **do**
    `/* Step 1: Encode states to latent space */`
    $z_t \leftarrow \phi_\theta(x_t)$, $z_{t+1} \leftarrow \phi_\theta(x_{t+1})$, $\forall (x_t, u_t, x_{t+1}) \in \mathcal{B}$;
    `/* Step 2: Compute reconstruction loss */`
    $\hat{x}_t \leftarrow \psi_\vartheta(z_t)$, $\hat{x}_{t+1} \leftarrow \psi_\vartheta(z_{t+1})$;
    $\mathcal{L}_{\text{recon}} \leftarrow \frac{1}{|\mathcal{B}|} \sum (\|x_t - \hat{x}_t\|^2 + \|x_{t+1} - \hat{x}_{t+1}\|^2)$;
    `/* Step 3: Compute linear dynamics loss */`
    $\hat{z}_{t+1} \leftarrow Az_t + Bu_t + Cw_t$;
    $\mathcal{L}_{\text{linear}} \leftarrow \frac{1}{|\mathcal{B}|} \sum \|z_{t+1} - \hat{z}_{t+1}\|^2$;
    `/* Step 4: Compute multi-step prediction loss */`
    $z_t^{(0)} \leftarrow z_t$;
    for $k = 1$ **to** K **do**
      $z_t^{(k)} \leftarrow A^k z_t + \sum_{j=0}^{k-1} A^{k-1-j}(Bu_{t+j} + Cw_{t+j})$;
      $\hat{x}_{t+k} \leftarrow \psi_\vartheta(z_t^{(k)})$;
    end
    $\mathcal{L}_{\text{pred}} \leftarrow \frac{1}{K|\mathcal{B}|} \sum_{k=1}^{K} \|x_{t+k} - \hat{x}_{t+k}\|^2$;
    `/* Step 5: Compute total loss */`
    $\mathcal{L}_{\text{total}} \leftarrow \lambda_{\text{recon}}\mathcal{L}_{\text{recon}} + \lambda_{\text{linear}}\mathcal{L}_{\text{linear}} + \lambda_{\text{pred}}\mathcal{L}_{\text{pred}}$;
    `/* Step 6: Update parameters via backpropagation */`
    $\theta \leftarrow \theta - \eta \nabla_\theta \mathcal{L}_{\text{total}}$;
    $\vartheta \leftarrow \vartheta - \eta \nabla_\vartheta \mathcal{L}_{\text{total}}$;
    $A \leftarrow A - \eta \nabla_A \mathcal{L}_{\text{total}}$;
    $B \leftarrow B - \eta \nabla_B \mathcal{L}_{\text{total}}$;
    $C \leftarrow C - \eta \nabla_C \mathcal{L}_{\text{total}}$;
  end
end
`/* Construct projection matrix */`
Collect latent states $Z = [z_1, \ldots, z_N] \in \mathbb{R}^{n_z \times N}$ and corresponding velocities and yaw rates $Y = [v, \omega]^\top \in \mathbb{R}^{2 \times N}$;
$D \leftarrow YZ^\top (ZZ^\top + \gamma I)^{-1}$; `/* Ridge regression for` $[v, \omega]^\top \approx Dz$ `*/`
return A, B, C, ϕ_θ, ψ_ϑ, D
